ABSTRACT

As generative artificial intelligence (GenAI) reshapes consumer–product interactions, understanding how consumer attention drives personalized experiences has become increasingly vital. This study examines how distinct attention configurations shape consumer satisfaction, offering new insights into AI-enabled product personalization. Using consumer reviews from leading GenAI applications, including ChatGPT, Copilot, and Gemini, we combine semantic analysis powered by large language models (LLMs) with configurational analysis to identify cognitive, emotional, and habitual attention patterns and their effects on consumer experience. The results show that hedonic motivation and habitual use are primary drivers of high satisfaction, while performance expectancy and effort expectancy exert complementary influence within specific configurations. Negative outcomes arise from misalignments between performance expectations and perceived price value, highlighting the importance of aligning experiential value with consumer expectations. By introducing consumer attention configurations as a marketing-oriented mechanism for personalization, this study proposes an experiential co-creation framework that enhances GenAI product design. The findings contribute to AI-driven service innovation research and offer actionable guidance for organizations seeking to develop emotionally engaging AI products that cultivate sustained consumer loyalty.

1 | Introduction

The rapid emergence of generative AI has transformed how digital products and services are designed, delivered, and experienced (Nasr and El-Deeb 2025; Peltier et al. 2024). Enabled by advanced deep neural network models capable of generating high-quality contents, GenAI systems such as ChatGPT, Microsoft Copilot, and Google Gemini are redefining interaction paradigms across entertainment, education, marketing, and professional domains (Grewal et al. 2025; Arora et al. 2025). Unlike conventional digital applications, GenAI systems provide dynamic, adaptive, and context-aware responses, enabling hyper-personalized interactions and positioning GenAI as both a technological breakthrough and a strategic enabler

of customer-centric service innovation (Huang and Rust 2018; Puntoni et al. 2021; Swan et al. 2024). This paradigm shift underscores a broader transition toward adaptive service ecosystems where value is co-created through continuous human-AI interaction (C. L. Wang 2026).

Despite the transformative potential of GenAI, its success ultimately hinges on how consumers perceive, interpret, and engage with AI-generated outputs (Gao and Liu 2023). However, such engagement is not automatic, it is mediated by consumers' selective attention (Janiszewski et al. 2013; Orquin and Wedel 2020). In AI-enabled services, personalization is therefore not merely a technical capability embedded in algorithms, but a co-creative cognitive process shaped by

how consumers allocate their attention during interaction (Chandra and Rahman 2024; Chopdar and Paul 2024). Acting as a cognitive bridge, attention determines which aspects of the AI service are processed. While some consumers prioritize perceived intelligence and functional sophistication, others focus on responsiveness, ease of interaction, or experiential features. Through this selective allocation of attention, consumers translate AI-driven personalization into subjective evaluations. Consequently, identical products may elicit markedly different perceptions and even opposing intentions for continued use.

Such variation arises from bounded rationality, possessing limited cognitive resources, consumers prioritize features they perceive as most relevant or rewarding (Loewenstein and Wojtowicz 2025). This leads to substantial heterogeneity in how AI-enabled products are noticed, processed, and evaluated (Rieser and Furneaux 2022; Ye et al. 2024). As GenAI applications expand their functional scope, they increasingly compete for consumers' scarce attentional resources, complicating the design of experiences that resonate with diverse consumer groups. While firms could theoretically meet heterogeneous needs by launching multiple product variations, doing so is costly and difficult to scale. Consequently, identifying how different consumers allocate attention has become essential for designing personalized yet scalable GenAI services (Zhang et al. 2022). Against this backdrop, this study poses the following research questions: How do consumers allocate attention across different GenAI features under bound rationality? And how do heterogeneous allocation patterns shape their subsequent product evaluations?

Existing studies have provided valuable insights into how technological attributes, usability factors, and perceived value influence consumers' adoption of emerging products and services (Zhang et al. 2022; Baabdullah et al. 2019; Bellman et al. 2011). These works have advanced understanding of key determinants such as performance expectancy, ease of use, and trust, offering important foundations for explaining consumer acceptance of emerging technologies. However, few studies have systematically examined how consumer attention configurations shape satisfaction and adoption in generative AI contexts. Prior research typically adopts variance-based approaches, such as regression or structural equation models, that estimate independent and additive effects, implicitly assuming linearity and causal symmetry among influencing factors. Such assumptions may be insufficient for capturing the complexity of GenAI consumer engagement, which reflects equifinality and causal asymmetry. High satisfaction can emerge from multiple distinct configurations of attention, and the pathways leading to dissatisfaction are not simply the opposite of those producing positive experiences. As highlighted by Tiwari et al. (2024), reliance on linear analytical frameworks may obscure conjunctural or necessary conditions that do not exhibit independent net effects in variance-based models.

To address these gaps, this study proposes a computational-interpretive framework that integrates attention theory, UTAUT2, and value co-creation perspectives. Using LLMs for guided topic modeling and configuration analysis, the study

identifies how different attention configurations jointly shape consumer satisfaction with GenAI APPs. This approach enriches existing AI-driven service research by uncovering multiple causal pathways to satisfaction and providing relevant marketing insights into designing emotionally engaging, consumer-centered AI services (Carew et al. 2025). The findings of this study underscore a nuanced view of how cognitive and affective processes interact in shaping satisfaction and advance the theoretical understanding of the research field (C. L. Wang 2024).

The remainder of this paper is organized as follows. Section 2 provides a literature review on consumer attention configurations, consumer adoption theory, and consumer satisfaction. Section 3 outlines the research framework and methodology. Section 4 presents the analysis of the research results. Section 5 discusses the theoretical and managerial implications. Finally, Section 6 highlights the study's limitations and provides directions for future research.

2 | Literature Review

2.1 | Consumer Attention in AI-Driven Personalization

Attention is a foundational mechanism that shapes individual preferences and decision making. Theoretically, this mechanism is underpinned by established frameworks such as Broadbent's Filter Model, which posits that attention acts as a bottleneck allowing only specific stimuli to be processed (Broadbent 1982), and Kahneman's Capacity Model, which conceptualizes attention as a limited mental resource that must be strategically allocated (Kahneman 2003). Consistent with these views, when an agent engages in continuous interaction with an object, the perception of certain features of the object intensifies, while the perception of other features diminishes (Janiszewski et al. 2013).

From a marketing and service innovation perspective, attention determines which elements of a digital experience consumers notice, process, and value, shaping how personalization unfolds in AI-driven contexts (Weiss 2022) that facilitate virality of marketing communication (Kaur et al. 2023). In service encounters mediated by generative AI, attention acts not merely as a passive filter but as an active input to adaptive learning systems (Mortati and Giovanna 2026). AI algorithms interpret consumer attentional cues, explicit or implicit, to tailor content and interactions in real time, effectively co-producing personalized experiences (Gao and Liu 2023; Huang and Rust 2018; Li et al. 2025). This co-adaptive process marks a shift from one-way personalization to AI-enabled experiential co-creation, where consumer attention dynamically informs system responses and service outcomes.

The selective nature of attention is particularly relevant to digital product and service adoption (Verschooren et al. 2019). Limited cognitive resources compel individuals to focus on the most salient features, guided by intrinsic motivations and external design cues (Alsharif et al. 2023). Developers thus design interfaces to direct attention toward functions that enhance

engagement and loyalty (Rieser and Furneaux 2022). Building on these insights, this study conceptualizes consumer attention configurations as patterns of selective focus on APPs features and experiential attributes during decision-making (Avoyan et al. 2023). While these configurations, observable in UGC (User-generated content), reveal how consumers allocate attention and evaluate AI-personalized experiences (Kar and Kushwaha 2023), the heterogeneity and informality of UGC necessitate advanced NLP approaches to uncover nuanced meanings (Rogers et al. 2022).

2.2 | AI-Enabled Technology and Service Adoption

Technology and service adoption theories provide structured explanations of how individuals decide to embrace new technologies or services. Traditionally, these frameworks emphasize rational evaluations of perceived benefits and risks, assuming consumers systematically assess all relevant factors (Fakhrhosseini et al. 2024). In reality, consumers' cognitive capacity and attention are limited, leading them to focus selectively on the most salient adoption cues (Ye et al. 2024). This selective process suggests that adoption is not uniform but arises from dynamic configurations of psychological, social, and contextual influences, particularly in AI-mediated service environments where personalization continuously evolves through interaction (Foroughi et al. 2025).

At the micro level, the Theory of Planned Behavior (Ajzen 1991) highlights belief-driven intentions, while Social Cognitive Theory (Bandura 1987) emphasizes reciprocal interactions between cognition, emotion, and behavior. The Technology Acceptance Model (Davis et al. 1989) identifies perceived usefulness and ease of use as core determinants but often overlooks experiential and contextual variables critical to consumer technologies. To integrate these perspectives, the Unified Theory of Acceptance and Use of Technology (Venkatesh et al. 2003) consolidates prior models around performance expectancy, effort expectancy, social influence, and facilitating conditions. However, its workplace focus limits its capacity to explain the affective, hedonic, and co-creative dimensions of AI-enabled service adoption.

The extended UTAUT2 model (Venkatesh et al. 2012) addresses these limitations by incorporating hedonic motivation, price value, and habit, thereby enhancing its predictive power in consumer contexts (Tamilmani et al. 2021). Although UTAUT2 identifies the key determinants that shape technology adoption (Baabdullah et al. 2019; Faqih and Jaradat 2021), it offers limited insight into how consumers allocate their cognitive and emotional attention during real interactions with AI-enabled services. To address this limitation and extend existing theories, the present study conceptualizes consumer attention as a cognitive-emotional mechanism that captures the dynamic process through which consumers selectively notice, process, and prioritize different product attributes (Florack et al. 2020). Attention allocation reflects the selective investment of limited cognitive resources in specific attributes, which subsequently shapes the formation of evaluative perceptions such as performance expectancy, hedonic motivation, or habit-related tendencies. Within this process,

UTAUT2 constructs are treated as observable evaluative outcomes shaped by underlying attentional focus. For example, forming a perception of performance expectancy presupposes that consumers have attended to the functional capabilities of an AI-enabled service, whereas hedonic motivation reflects sustained affective engagement with experiential aspects of the service. In this sense, perceptions associated with UTAUT2 dimensions can be understood as reflective manifestations of attention directed toward attributes, enabling us to infer attention configurations through their patterned co-occurrence. Whereas UTAUT2 theoretically emphasizes the determinants of individual adoption, attention configurations capture the combinatorial structure through which cognitive, affective, and habitual foci jointly emerge and influence satisfaction outcomes. From this perspective, the adoption of AI-enabled services is understood not merely as a rational decision, but as an evolving hedonic motive or experiential process shaped by dynamic attention allocation (Shao 2025; Venkatesh et al. 2012).

2.3 | Consumer Satisfaction in AI-Driven Product Innovation

Consumer satisfaction reflects an individual's overall evaluation and emotional response to their experience with a product or service. In digital and AI-enabled environments, satisfaction represents not only a cognitive assessment of system performance but also an affective judgment shaped by personalized, adaptive interactions (Sharma et al. 2026). For mobile applications, satisfaction remains a key predictor of continued usage, loyalty, and word-of-mouth behavior (Tam et al. 2018). In generative AI services, satisfaction arises when the system delivers timely, reliable, and contextually relevant responses that meet consumer expectations for intelligence and personalization (Grewal et al. 2025). Conversely, inconsistent performance or low perceived intelligence can disrupt trust and reduce engagement, undermining both consumer retention and perceived service quality. Consequently, satisfaction is not a uniform outcome but is contingent upon the consumer's specific attention focus. Since consumers possess limited cognitive resources, their satisfaction is primarily determined by the performance of the attributes they actively attend to. Different attention configurations will lead to distinct satisfaction outcomes, as consumers weigh product attributes differently based on their allocation of attention.

Prior research has examined consumer satisfaction across multiple dimensions, including brand attitude (Bae and Kim 2023), omnichannel consumer journey (Moliner and Tortosa-Edo 2024), interpersonal recommendations (Xu et al. 2015), cultural values (Hoehle et al. 2015), consumer engagement (Bitrián et al. 2021; Sussman et al. 2023), consumer virtual experience (Yao and Ren 2025), and perceived value (Akdim et al. 2022). Extending these perspectives, integrative frameworks such as the Expectation Confirmation Model combined with UTAUT2 (Tam et al. 2018) and the IS Continuance Model (Yan et al. 2021) highlight that satisfaction drives consumers' long-term commitment to digital services. However, these models typically assume that consumers evaluate factors independently, overlooking how

FIGURE 1 | Consumer attention configuration analysis framework. (a) RoBERTa, Robustly Optimized BERT Pretraining Approach, (b) Llama 3.2, Large Language Model Meta AI. *Source:* Inspired by Lee (2022) and Lee et al. (2024).

different experiential attributes interact to shape satisfaction in AI-driven products. Therefore, understanding satisfaction in GenAI requires examining how it is shaped by heterogeneous attention configurations.

3 | Research Methodology

3.1 | Research Design and Data Collection

3.1.1 | Research Framework

This study focuses on examining how consumer attention shapes personalized experiences in AI-driven products. Attention functions as a behavioral bridge between human perception and AI-enabled personalization, influencing how consumers co-create value in adaptive service interactions. Rather than treating attention as an isolated predictor, we conceptualize it as patterned combinations of cognitive-emotional force that jointly constitute sufficient pathways to satisfaction.

To capture this combinatorial and asymmetric logic, we develop an AI-assisted configurational framework that integrates configuration analysis with fine-tuned LLM models. By analyzing user reviews, the framework identifies multiple attention

configurations that jointly drive satisfaction, rather than estimating the independent net effects of individual factors (Kumar et al. 2023; tom Dieck et al. 2023). Accordingly, this study adopts a mixed-method design that combines computational analysis with interpretive reasoning, ensuring methodological alignment with the complexity of GenAI consumer engagement while maintaining analytical rigor and marketing relevance (Chopdar et al. 2022).

The overall framework, illustrated in Figure 1, consists of four interrelated stages designed to uncover how consumer attention patterns shape satisfaction in AI-driven products. In the first stage, UGC in the form of user reviews was collected from leading GenAI applications. These reviews provide authentic, naturally occurring insights into consumer experiences. The second and third stages aim to uncover consumers' cognitive-emotional attention patterns and experiential evaluations. The second stage focuses on identifying latent themes that reflect how consumers allocate attention to functional, hedonic, and social attributes of AI services. In parallel, the third stage evaluates consumer satisfaction by analyzing emotional tone and evaluative language in reviews, complementing numerical ratings with nuanced sentiment insights. Finally, the fourth stage integrates these analytical outcomes within a configurational framework using configuration analysis. This stage examines

FIGURE 2 | Construction of seed word sets for Human-AI collaboration.

how distinct attention configurations jointly lead to differences in satisfaction, thereby bridging computational insights with behavioral interpretation.

3.1.2 | Data Collection and Preprocessing

To ensure a representative analysis, three popular generative AI mobile applications (OpenAI ChatGPT, Microsoft Copilot, Google Gemini) were selected. Their market prominence is substantiated by Google Play statistics, with each application exceeding 50 million cumulative downloads as of January 2025. These APPs were chosen based on their market prominence, high user engagement, and distinct functionalities. There are two key advantages to this selection: first, all three are pre-trained generative chat applications, facilitating a horizontal comparison; second, their high market visibility and user engagement not only enabled the collection of user review data for the study but also enhanced the representativeness of the research findings. Notably, this methodology can also be applied to other GenAI applications. In total, 57,969 English-language consumer reviews were collected between May 2023 and October 2024. To ensure data quality, duplicates and irrelevant entries were filtered out using an automated Python script, resulting in 57,681 valid reviews retained for analysis.

UGC provides a rich and naturally occurring source of consumer feedback, offering authentic evaluations of satisfaction, perceived value, and experiential quality. However, such content is inherently unstructured and noisy, often containing spelling errors, colloquial expressions, and incomplete sentences (Rogers et al. 2022). To address these challenges and ensure interpretive accuracy, a semantic preprocessing procedure was implemented to clean, standardize, and normalize text while preserving original meaning. This process leveraged LLM to refine informal language, correct grammatical inconsistencies, and enhance coherence without distorting consumer intent (De-Fitero-Dominguez et al. 2024). Integrating LLM-based refinement into the preprocessing pipeline ensured high-fidelity reconstruction of consumer expressions, thereby improving the semantic validity of the

dataset for subsequent analysis of attention patterns and satisfaction. We utilized Unsloth to achieve fine-tuning objectives, which included: (a) removing irrelevant elements such as HTML tags and special characters, (b) correcting spelling errors and eliminating redundancies, and (c) normalizing contractions by expanding abbreviations.

3.2 | Attention Configuration Recognition Based on Guided Topic Model

To uncover consumers' underlying attention structures, this study employs a guided topic modeling approach that combines machine learning interpretability with theory-driven guidance. Unlike conventional unsupervised models that rely solely on statistical co-occurrence, this method incorporates semantic anchors derived from UTAUT2 constructs to align emergent themes with established adoption dimensions. By combining computational precision with theoretical grounding, this process transforms text clustering into behaviorally meaningful insights into how consumers perceive and co-create value with AI-enabled services. The output of this stage is an attention configuration matrix, serving as the antecedent condition for subsequent configuration analysis of satisfaction outcomes.

3.2.1 | Seed Word Development

Guided topic modeling begins with the development of seed words representing the seven UTAUT2 constructs. Following Tamilmani et al. (Tamilmani et al. 2021), these constructions serve as prior knowledge to enhance both the control and interpretability of the model. As illustrated in Figure 2, seed word generation proceeded in three steps: (a) AI-Assisted Generation: Initial lists of candidate terms were generated via LLM-assisted prompts applied to a random subset of reviews to capture emergent semantic patterns. (b) Expert Refinement: To clarify construct boundaries, a hybrid panel of five experts, comprising two scholars and three senior AI product managers, was assembled to ensure the lexicon aligned with both UTAUT2 theoretical constructions and authentic user

contexts. Following a structured protocol, the experts defined extraction perspectives, independently evaluated terms for conceptual representativeness and semantic uniqueness, and finalized the selection through a majority rule consensus to rigorously eliminate ambiguity. (c) Frequency Filtering: To ensure empirical representativeness, terms appearing with low frequency (e.g., word frequency less than 10) in the corpus were excluded. This filtration step minimized noise from idiosyncratic expressions.

3.2.2 | Topic Assignment and Validation

Each review was encoded into semantic vectors using the allmpnet-base-v2 sentence transformer model, selected for its superior performance in semantic clustering tasks. BERTopic (Version 0.16.4) (Grootendorst 2022) was then applied to cluster reviews into semantically coherent subtopics. Compared to traditional probabilistic models, this approach captures nuanced cognitive–emotional distinctions in consumer discourse, producing interpretable themes aligned with consumer experience attributes. Regarding the determination of the topic count, the number of subtopics was determined dynamically by the underlying HDBSCAN algorithm, which identifies dense clusters within the high-dimensional semantic vector space. To ensure optimal granularity, we adjusted key hyperparameters (specifically, min cluster size and min samples) to ensure that the resulting themes were both statistically robust and semantically interpretable.

To map subtopics to UTAUT2 constructs, cosine similarity was computed between topic feature words and predefined seed words. The category with the highest similarity score was assigned to each subtopic. This procedure generated an attention distribution matrix, reflecting the probabilistic alignment of each review with the seven UTAUT2 dimensions. Aggregating these distributions revealed latent attention configurations, illustrating how consumers selectively attend to functional, hedonic, and social attributes when interacting with AI-enabled services. This stage bridges computational text analytics and marketing theory, translating machine-derived patterns into actionable insights for personalization, engagement, and value co-creation. Specifically, for each subtopic, we computed the average cosine similarity of its feature words with the seed words from each UTAUT2 category. The category with the highest average similarity was then assigned to the subtopic. This process is mathematically represented as follows:

$$\text{Category index} = \underset{c}{\operatorname{argmax}} \left(\frac{1}{d} \sum_j \left(\underset{p_{i,j} \in P_i; q_{k,c} \in Q_c}{\operatorname{top}_d} \left(\frac{p_{i,j} \cdot q_{k,c}^T}{\|p_{i,j}\| \|q_{k,c}\|} \right) \right) \right) \quad (1)$$

where $p_{i,j} \in P_i$ represents the word vector of the keyword j in subtopic i , and $q_{k,c} \in Q_c$ represents the word vector of the seed word k in category c . To determine which UTAUT2 category subtopic i belongs to, the average of the top d cosine similarity scores is computed between all keyword vectors in P_i and all seed word vectors in Q_c . The category with the highest average similarity score is assigned to the subtopic. Additionally,

BERTopic allows for the direct extraction of subtopic distribution probabilities for each individual review. By aggregating these subtopic distribution probabilities, we can derive the latent probability distribution of the review across the UTAUT2 categories.

3.3 | Consumer Satisfaction Calculation Based on Sentiment Analysis

Consumer satisfaction reflects the overall affective evaluation of interactions with a product or service. While numerical APP ratings provide a basic indicator, they often fail to capture the nuanced emotions embedded in consumer experiences (Meister and Reinholtz 2025). To address this limitation, we employed sentiment analysis to operationalize satisfaction based on text-based user-generated content. The approach identifies the polarity of emotional expressions within the text, thereby serving as a robust proxy for gauging the level of user satisfaction with specific products or services (Kang and Park 2014; Chang et al. 2022).

The twitter-roberta-base-sentiment-latest model, a RoBERTa-base variant fine-tuned on the TweetEval benchmark dataset, was adopted for sentiment analysis (Loureiro et al. 2022). This model was chosen for its linguistic alignment with the informal nature of user reviews, derived from its training on social media corpora. To validate its applicability, we manually annotated 1000 sample reviews from the preprocessed dataset. The model achieved high reliability with an accuracy of 87.2% and an F1-score of 88.9%, significantly outperforming a traditional lexicon-based baseline (NLTK), which achieved only 74.3% accuracy and 76.4% F1-score on the same dataset. This result confirms the model's superior capability in interpreting context-rich consumer discourse. Each review was classified into positive, negative, or neutral sentiment, and probability-weighted scores were used to generate a continuous measure of satisfaction. To enhance interpretive clarity and ensure the robustness of the configurational analysis, reviews with neutral sentiment or low classification confidence were excluded (Lee 2022; Lee et al. 2024). Although this filtering procedure may introduce a degree of selection bias by omitting ambiguous or indifferent consumer feedback, it was necessary to rigorously distinguish between states of satisfaction and dissatisfaction in personalized consumer experiences. The resulting refined sentiment measure was used as the outcome variable, ensuring that subsequent configurational analyses relied on high-fidelity signals rather than equivocal data.

3.4 | Configuration Analysis

To examine how different combinations of consumer attention factors jointly shape satisfaction, this study employs fuzzy-set qualitative comparative analysis (fsQCA). This method is particularly suited for identifying complex, non-linear, and asymmetric causal relationships that traditional regression models often overlook (Pappas and Woodside 2021) to uncover multiple pathways through which cognitive–emotional attention patterns influence satisfaction in AI-driven service contexts.

We employed fsQCA 4.1 to analyze how consumer attention dimensions derived from guided topic modeling influence consumer satisfaction. These attention dimensions were treated as antecedent conditions, while consumer satisfaction served as the outcome. Following standard fsQCA procedures (Pappas and Woodside 2021; Paul and Kaurav 2025), all variables were calibrated into fuzzy sets using the 75th, 50th, and 25th percentiles of each dimension as anchors for full membership, crossover, and full non-membership, respectively. Prior to the configurational analysis, a necessity test was conducted. Results indicated that no single feature constitutes a necessary condition for either positive or negative sentiment, reinforcing the premise that satisfaction results from the combination of multiple factors rather than any single determinant. Consequently, a truth table was constructed to analyze sufficient configurations. To ensure analytical rigor and theoretical relevance, the thresholds were set at raw consistency = 0.75, PRI consistency = 0.70, and frequency = 5. The final analysis revealed multiple equifinal configurations leading to high satisfaction, confirming that satisfaction emerges from the synergistic interplay of cognitive, emotional, and habitual attention components rather than independent factors.

4 | Results Analysis

4.1 | Fine-Tuned Models for Text Proofreading

To ensure the accuracy and interpretive reliability of UGC, a fine-tuned LLaMA 3.2 model was employed for text proofreading. This step was essential for mitigating linguistic noise inherent in UGC, such as informal expressions, grammatical inconsistencies, and abbreviations, thereby improving the semantic clarity of the dataset. Parameter optimization was conducted to achieve an effective balance between model accuracy and

computational efficiency. During the parameter tuning process, several key factors were addressed to ensure optimal performance. These include the learning rate, batch size, and maximum training steps. The learning rate was gradually adjusted to prevent overfitting, with a final value of 0.0001 identified for achieving the highest accuracy. The batch size was optimized to 4, and the maximum number of training steps was set to 125, balancing computational efficiency and model stability. However, limitations were observed in handling highly ambiguous sentences or those containing mixed languages, suggesting the need for additional refinement in future iterations.

Nevertheless, LLM-based processing entails inherent risks of bias, particularly the potential for over-smoothing unique consumer expressions or inadvertently altering sentiment polarity. To mitigate these risks, a conservative fine-tuning strategy was implemented, prioritizing semantic preservation over stylistic standardization. Furthermore, rigorous human validation was performed to ensure reliability. Evaluation was performed on a random subset of consumer reviews ($n = 500$), where three independent researchers manually compared the original and proofread texts. The fine-tuned model achieved an average proofreading accuracy across three validation rounds exceeding 99%, as shown in Figure 3. This human-in-the-loop verification process confirmed that the refined model significantly improved the linguistic quality of the dataset while preserving the authentic voice of the consumers. Following this human validation, the fine-tuned LLaMA model was applied to the entire corpus.

4.2 | Extraction of Attention Configuration

To identify the key structures of consumer attention configuration, this study employed a guided topic modeling approach using BERTopic. This technique enables the identification of

FIGURE 3 | Fine-tuning log of LLaMA for text proofreading.

latent configuration, reflecting how consumers cognitively and emotionally engage with various aspects of AI-enabled services.

4.2.1 | Guided Topic Model Setup

A stratified random sample of 5000 preprocessed reviews was analyzed by LLaMA 3.2 for keyword extraction aligned with the UTAUT2 constructs. This process ensured that both functional and experiential aspects of consumer attention were adequately captured. Cosine similarity was then computed between seed words and subtopic feature words to establish theoretical alignment. Expert review and frequency filtering further refined the seed lists by removing overly general or low-coverage terms (occurring in fewer than 50 reviews). The final seed sets, summarized in Table 1, provided the conceptual anchors for guided topic modeling.

4.2.2 | Topic Distribution

Each subtopic generated by BERTopic was mapped to the UTAUT2 construct with the highest mean cosine similarity among its top three matches. This procedure enabled conceptually overlapping subtopics to be jointly represented, capturing the multidimensional nature of consumer attention. The aggregated assignments yielded a probabilistic attention distribution for each consumer review, reflecting the relative influence factors on engagement with AI-enabled services. As illustrated in Figure 4, attention was unevenly distributed across the seven UTAUT2 constructs. Using a uniform allocation as a theoretical baseline, a construct was deemed to receive concentrated attention if its share exceeded one-seventh of total attention. Figure 4a shows that most consumers focused on two to three constructs rather than engaging all dimensions equally, while Figure 4b presents the frequency distribution of attention scores, where the x-axis represents the probability of attention

TABLE 1 | Seed word statistics.

Topic	Seed words count (model selected)	Seed words count (expert refined)	Seed words count (final filtered)	Representative seed words	Seed words coverage
Performance expectancy	39	30	18	'help', 'answer', 'write', 'result', 'improvement'	33.44%
Effort expectancy	57	31	23	'easy', 'quick', 'smooth', 'simple', 'clear'	18.85%
Social influence	35	30	12	'family', 'friend', 'social', 'advice', 'trust'	9.08%
Facilitating conditions	64	30	17	'update', 'support', 'bug', 'account', 'guidance'	12.67%
Hedonic motivation	63	33	18	'amazing', 'fun', 'exciting', 'interesting', 'engage'	12.19%
Price value	75	31	15	'cheap', 'free', 'pay', 'worth', 'cost'	16.34%
Habit	55	27	17	'regular', 'daily', 'reliable', 'constant', 'natural'	12.93%

FIGURE 4 | Consumer attention frequency.

allocation categorized into intervals (bin size = 0.1). The distribution of attention scores reveals a distinct skew toward lower values, indicating that for any given dimension, high-intensity attention is rare.

Performance Expectancy, Hedonic Motivation, and Effort Expectancy attracted disproportionate attention, suggesting that evaluations of GenAI mobile applications hinge on functional effectiveness, experiential enjoyment, and ease of interaction. These focal points underscore consumers' strategic allocation of cognitive resources toward attributes that maximize perceived value. Overall, consumer attention emerges as selective and goal-directed, favoring dimensions that deliver functional efficiency and emotional gratification.

4.3 | Detection of Consumer Satisfaction

As outlined in the methodology section, the sentiment analysis initially categorized all reviews into three classes: positive, neutral, and negative. A strong correlation was observed between sentiment labels and consumers' star ratings, as shown in Figure 5a. Most high-star reviews were classified as expressing positive sentiment, while lower-star reviews were predominantly labeled as negative. However, discrepancies were noted in cases where some high-star reviews were classified as negative, which could be attributed to contradictory consumer ratings or errors in the sentiment analysis model.

To address ambiguities and ensure high classification confidence, a probability threshold was applied to filter the dataset. The RoBERTa-base sentiment analysis model provided not only sentiment labels but also confidence probabilities for each prediction. Specifically, reviews with sentiment probabilities below 70% were excluded from further analysis. This threshold was empirically determined through a sensitivity analysis conducted on the validation set. We tested thresholds ranging from 0.1 to 1.0 (with a step size of 0.1) and evaluated the trade-off between model performance metrics (Accuracy and F1-score) and data retention. The 0.7 threshold was identified as the optimal point, maximizing classification reliability while minimizing the exclusion of valid data. The sentiment distribution after filtering

is presented in Figure 5b. 77.22% of the samples were retained, leading to a significant reduction in the occurrence of conflicts between star ratings and emotional orientation. This filtering strategy effectively mitigates limitations inherent in relying solely on either star ratings or sentiment analysis, thereby enhancing the robustness.

4.4 | Consumer Attention Configuration Analysis Results

The configuration analysis based on the UTAUT2 framework identifies how combinations of consumer attention factors jointly shape emotional outcomes reflected in review sentiment. Although the attention distribution is highly left skewed in Figure 5b, calibration assumed an idealized consumer allocating attention evenly across all UTAUT2 constructs, ensuring equal weighting of features during set construction.

4.4.1 | Overall Configuration Analysis

Under a consistency threshold of 84.31%, 59.02% of the samples revealed seven configurations, representing consumer groups whose attention focused on different features and exhibited relatively positive sentiment. In contrast, no configurations were identified from the samples with negative satisfaction. The truth table analysis is presented in Table 2. The black solid circle (●) indicates the presence of a condition, the black dotted circle (⊙) indicates marginal presence, the empty circle (○) represents an irrelevant condition, the circle with a single diagonal line (⊘) indicates marginal absence, and the circle with a cross (⊗) represents the absence of a condition. The seven high-satisfaction configurations reveal multiple, equifinal pathways through which consumers experience positive emotions. Most configurations highlight *Hedonic Motivation* and *Habit* as dominant antecedents; consumers who derive enjoyment from GenAI interactions and integrate them into daily routines are more likely to sustain satisfaction. This pattern corresponds with findings from the topic modeling stage, where consumers frequently describe lightweight, goal-oriented usage contexts. In these cases,

enjoyment and familiarity rather than instrumental conditions drive satisfaction.

From the perspectives of raw and unique coverage, configuration AIP1 exhibits the strongest explanatory power. Consumers low in sensitivity to *Facilitating Conditions* or *Price Value* but high in *Hedonic Motivation* tend to report the most positive experiences—suggesting that emotional gratification outweighs cost considerations in the mobile GenAI context. Similarly, consumers who have developed habitual engagement (configurations AIP2–AIP5) also report sustained satisfaction, consistent with behavioral reinforcement effects. The guided topic modeling further confirms that seed terms linked to *Habit* strongly align with these consumer segments. Two additional configurations, AIP6 and AIP7, emphasize *Effort Expectancy* and *Performance Expectancy* as satisfaction drivers. The former represents consumers attentive to ease of use and minimal learning effort, while the latter reflects those valuing tangible task benefits. These findings collectively suggest that satisfaction with GenAI mobile applications is not determined by any single construction but by distinct constellations of cognitive, emotional, and habitual attention. This multi-path perspective reinforces the idea that consumer satisfaction in AI-driven services is configurational and experience-based.

4.4.2 | Individual Configuration Analysis

To obtain finer-grained insights into how consumer attention configurations vary across applications, separate fsQCA analyses were conducted for OpenAI ChatGPT, Microsoft Copilot, and Google Gemini. The results are summarized in Table 3. Using the same calibration and threshold parameters as in the overall model, no high-satisfaction configurations were identified for Google Gemini, whereas three configurations emerged for negative sentiment. Although Gemini's configurational coverage is lower than that of ChatGPT and Copilot, the satisfactory consistency levels confirm the robustness of the findings. This discrepancy underscores meaningful cross-APP heterogeneity,

suggesting that consumer satisfaction mechanisms may depend on distinct experiential and technological factors.

The configurational results for ChatGPT and Copilot (Table 3A,B) display substantial overlap, a logical outcome given their shared technological foundation, as Copilot integrates OpenAI's GPT-4 model. Despite differences in branding and integration contexts, both applications deliver comparable service quality, leading to parallel patterns of consumer attention and satisfaction. Across most configurations, *Hedonic Motivation* and *Habit* dominate as core causal conditions, while *Facilitating Conditions* are largely absent. This suggests that consumers' satisfaction is primarily derived from intrinsic service experiences rather than external enablers like device compatibility or technical support. From a marketing perspective, this finding implies that firms should prioritize intuitive interface design, fluid consumer interaction, and emotionally engaging experiences to foster long-term attachment and satisfaction.

A nuanced divergence from the aggregate analysis emerges in consumers' heightened attention to *Effort Expectancy* across multiple ChatGPT and Copilot configurations (e.g., ChP7, ChP10–11; CoP8–10). These configurations reflect consumers' appreciation for ease of use and reduced cognitive load, reinforcing the role of frictionless interaction in shaping positive emotional outcomes. In contrast, *Social Influence* appears only in isolated configurations (ChP12, CoP11), likely due to the applications' established reputations from their desktop versions. Many consumers may have adopted mobile APPs independently for convenience rather than peer recommendation, diminishing the influence of social cues.

Interestingly, *Performance Expectancy* features more prominently in ChatGPT configurations (e.g., ChP5–6) than in Copilot. This differentiation likely stems from OpenAI's deployment strategy: ChatGPT frequently integrates the most advanced GPT versions earlier, enhancing perceived capability and intelligence relative to Copilot. The distinction reveals how technological leadership directly translates into consumer-perceived

performance and satisfaction, an insight valuable for AI service differentiation and competitive positioning.

By contrast, the configurational results for Google Gemini reveal a concentration of negative sentiment patterns, as reported in Table 3C. Three configurations (particularly GeN2) are associated with dissatisfaction when attention is jointly allocated to *Performance Expectancy*, *Effort Expectancy*, and *Price Value*, suggesting a pronounced misalignment between consumers' evaluative expectations and experienced outcomes along these dimensions. Rather than indicating absolute product inferiority, these configurations point to situations in which functional expectations are not sufficiently met to sustain positive evaluations. In addition, the absence of *Hedonic Motivation* in configurations GeN1 and GeN3 implies that limited emotional engagement may exacerbate dissatisfaction when utilitarian expectations dominate attention allocation. Complementary sentiment and rating evidence in Table 4 is consistent with this interpretation, showing lower average evaluations for Gemini relative to other GenAI applications. This finding aligns with prior case studies regarding the distinct market positioning and performance variances among these platforms (Rane et al. 2024). Taken together, these findings suggest that when high functional expectations are salient, but experiential or affective rewards are insufficient, negative consumer evaluations are more likely to emerge in AI-enabled service contexts.

5 | General Discussion

5.1 | Theoretical Contributions

This study contributes to the literature on AI-driven marketing, service personalization, and consumer experience by advancing understanding of consumer attention as both a resource and a mechanism in AI-enabled personalization and co-creation.

First, the study introduces the concept of consumer attention configuration as a comprehensive lens for understanding how cognitive, emotional, and habitual processes jointly shape satisfaction with AI-enabled services. Moving beyond prior research that treats attention as a static factor, we conceptualize attention as an active mechanism through which AI-driven personalization efforts are translated into consumer evaluations. This perspective provides a more nuanced, process-oriented account of consumer experience in AI-mediated contexts. It also aligns with

emerging research on psychological tensions in consumer-AI interactions (Puntoni et al. 2021), suggesting that satisfaction may reflect how consumers interpret AI-enabled experiences along dimensions such as feeling “served” versus “exploited” or “understood” versus “misunderstood.”

Second, the study extends the widely adopted UTAUT2 framework by reinterpreting its constructs as dimensions of attention allocation rather than as isolated predictors. Moving beyond the traditional linear view of UTAUT2, which assumes independent and additive effects, we adopt a configurational perspective that highlights causal complexity. This perspective underscores the interdependence and synergy among multiple factors, suggesting that consumer satisfaction emerges from specific combinations of conditions rather than from any single determinant. For instance, high performance expectancy may enhance satisfaction only when combined with other attributes such as hedonic motivation, a nuance often overlooked in variable-oriented approaches.

Third, the study develops a computational–interpretive framework that integrates fine-tuned LLMs with configuration analysis, providing a robust approach to extract, structure, and analyze unstructured consumer text data. This framework enables the identification of latent attention patterns that are not readily observable through traditional survey-based methods. By linking semantic modeling with configurational reasoning, the approach uncovers multiple causal pathways to consumer satisfaction, offering both theoretical insights and practical guidance for designing more effective AI-driven personalization strategies (C. L. Wang 2025a).

5.2 | Managerial Implications

From a managerial perspective, this study provides actionable guidance for enhancing consumer engagement, satisfaction, and retention in AI-driven services. It offers a practical framework for translating behavioral insights into adaptive and engaging GenAI APP designs.

First, attention configuration serves as a diagnostic and predictive tool for identifying which product features and service elements consumers value most. By examining how attention is distributed across cognitive and emotional dimensions, firms can infer underlying preference profiles that are not directly observable. For example, users whose attention centers on price value may respond more favorably to tiered subscription models or communications emphasizing return on investment, whereas users whose attention is oriented toward hedonic motivation are more likely to engage with creative or entertainment focused use cases. Importantly, many users exhibit hybrid attention patterns in which multiple dimensions are simultaneously salient. This alignment enables firms to deliver more precisely targeted content, thereby enhancing perceived relevance and consumer satisfaction.

Second, the findings emphasize the critical role of designing for sustained attention in AI-enabled service environments. Emotional appeal, ease of interaction, and habitual engagement emerge as primary pathways through which satisfaction

and loyalty are cultivated. Crucially, the allocation of individual cognitive resources often initiates with uncertainty reduction during early interactions. As evidenced by recent research (Tiwari et al. 2024), trialability serves as a necessary precondition for perceived ease of use. In the context of GenAI services, this implies that providing mechanisms for low-cost feature exploration is a pivotal antecedent for activating consumers' cognitive attention. Managers and developers can leverage these insights to create frictionless, habit-forming user experiences, ensuring that initial adoption translates into enduring engagement. By intentionally shaping attention pathways, firms can foster long-term relationships that are rooted in co-created personalized value rather than one-time transactional interactions. However, engagement strategies should be implemented with strong ethical safeguards. Firms need to avoid manipulative practices that exploit users' cognitive vulnerabilities and instead ensure that habit formation respects consumer autonomy and supports long-term user well-being.

Third, with respect to feature prioritization, incorporating attention analytics allows organizations to align product development roadmaps more closely with evolving user priorities. Our configurational results indicate that utilitarian factors, such as performance expectancy, primarily function as hygiene conditions that prevent dissatisfaction, whereas hedonic factors act as key drivers of high satisfaction. Accordingly, firms should first allocate R&D resources to establish a robust functional baseline, such as response accuracy and speed, to mitigate churn risks before investing heavily in peripheral features. Beyond this baseline, attention-informed insights enable firms to dynamically adjust feature rollouts by targeting specific bottleneck attributes identified in ongoing user feedback, such as deficits in emotional engagement. In this way, attention analytics support more adaptive and strategically differentiated AI services while enhancing retention and long-term user value.

5.3 | Limitations and Future Research

Although this study offers novel insights into how consumer attention configurations shape satisfaction in AI-driven mobile services, several limitations present promising directions for future research (Paul et al. 2023; C. L. Wang 2025b).

First, the empirical scope of the study is bounded by data source, application context, and platform coverage. The dataset relies exclusively on English-language reviews from Google Play and the Apple App Store within a specific time frame and focuses on general-purpose GenAI assistant applications in mobile environments. These design choices may limit generalizability across linguistic regions, alternative application ecosystems, domain-specific AI services, and cross-platform contexts (e.g., web or desktop interfaces). Future research could extend the analysis longitudinally, across languages, application categories, and platforms to better capture the evolving dynamics of consumer attention and satisfaction in diverse AI service ecosystems.

Second, methodological limitations relate to the use of LLMs for text normalization. Although the model was fine-tuned using manually annotated data and validated on a held-out test set, automated preprocessing may still attenuate subtle linguistic

nuances due to inherent model stochasticity. While the configurational analysis relies on patterned co-occurrence across conceptual dimensions rather than micro-level lexical intensity, future studies may adopt hybrid human-AI validation approaches or more interpretable models to further enhance robustness.

Third, the exclusion of neutral and low-confidence reviews enhances outcome clarity for configurational analysis but narrows the scope of inference to clearly balance satisfaction and dissatisfaction states. As a result, the findings may not fully capture ambivalent or low-intensity consumer experiences. Future research could explicitly investigate transitional or neutral evaluative states to deepen understanding of attention configurations under conditions of evaluative ambiguity.

6 | Conclusions

This study provides a comprehensive understanding of how consumer attention configurations shape satisfaction in generative AI mobile applications. The results reveal that consumers' satisfaction is not determined by isolated technological factors but by specific combinations of cognitive, emotional, and habitual elements that define their experiential engagement. These findings can be further interpreted in light of the psychological tensions inherent in consumer-AI interactions (Puntoni et al. 2021). High-satisfaction configurations appear consistent with conditions that reduce perceptions of exploitation or misclassification by enhancing perceived usefulness, ease, and experiential fulfillment. Conversely, dissatisfaction configurations may align with contexts in which such tensions become more salient, particularly when expectations are misaligned or experiential value is diminished. Empirically, generate three key findings:

1. Core attention drivers of satisfaction.

Hedonic Motivation, Habit, Performance Expectancy, and Effort Expectancy consistently dominate high-satisfaction configurations. Consumers who derive enjoyment and emotional fulfillment from GenAI applications, especially through seamless and intuitive interactions, report stronger satisfaction and continued engagement. Habitual use further reinforces satisfaction over time, reflecting the self-reinforcing nature of experiential co-creation. Interestingly, satisfaction rarely results from the simultaneous emphasis on *Performance Expectancy* and *Effort Expectancy*, implying that consumers prioritize either efficiency or ease of use, but seldom both concurrently.

2. The impact of product differences.

Cross-APP comparisons indicate that dissatisfaction commonly arises from unmet expectations concerning *Performance Expectancy*, *Effort Expectancy*, *Price Value*, or *Facilitating Conditions*. Consumers show strong sensitivity to discrepancies between promised and actual capabilities, underscoring the importance of value alignment and expectation management. For marketers and GenAI developers, ensuring transparent communication, consistent consumer experience, and credible signaling of product performance is critical for fostering satisfaction and trust (Arya et al. 2022).

3. Evolving role of social influence.

Although *Social Influence* appears marginally across most configurations, this pattern aligns with theoretical expectations regarding diffusion dynamics and the usage context of GenAI. Consistent with prior research (Chopdar et al. 2022; Purohit and Arora 2022), while social norms drive early adoption under high uncertainty, their impact diminishes as usage transitions from novelty-driven trial to routine, experience-based engagement. Furthermore, unlike conspicuous technologies, GenAI usage is inherently private, individualized, and task oriented. This lack of social visibility limits normative pressure, shifting the primary drivers of satisfaction from external social validation to personally experienced functional and hedonic value. Consequently, these findings reflect a broader evolution toward individualized, co-creative digital consumption.
